## 1 Equations

### 1.1 Bin's Papers

Our major references will be Bin's paper with Diego + Dong in 2015 (LML15) and Bin's later paper with Dong on spin-orbit misalignment (LL18). The target of study is §4.3 of LL18, where a 90° attractor in spin-orbit misalignment seems to appear when the octupole effect is negligible.

The easiest formulation is just to express everything in terms of  $\mathbf{L}$  and  $\mathbf{e}$ , following LL18. We drop octupole terms and hold the third perturber constant. These equations come out to be (Eqs. 4–5 w/ substitutions)

$$\frac{d\mathbf{L}}{dt} = \frac{3}{4t_{LK}} \mu \sqrt{Gm_{12}a} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2) - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2)], \quad (1)$$

$$\frac{d\mathbf{e}}{dt} = \frac{3}{4t_{LK}} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2) + 2\mathbf{j} \times \mathbf{e} - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2)]. \quad (2)$$

Note that  $\mathbf{j} \equiv \sqrt{1-e^2} \hat{\mathbf{L}} = \frac{\mathbf{L}}{\mu \sqrt{Gm_{12}a}}$ .  $m_{12} = m_1 + m_2$  and  $\mu = m_1 m_2 / m_{12}$ . We've defined

$$t_{LK} \equiv \frac{L_1}{\mu_1 \Phi_0} = \frac{1}{n_1} \left( \frac{m_{12}}{m_3} \right) \left( \frac{a_2}{a} \right)^3 (1-e_2^2)^{3/2}. \quad (3)$$

Here,  $n_1 \equiv \sqrt{Gm_{12}/a^3}$ . Thus,  $1/t_{LK} \propto a^{3/2}$ .

GW radiation (Peters 1964) cause decays of  $\mathbf{L}$  and  $\mathbf{e}$  as

$$\left. \frac{d\mathbf{L}}{dt} \right|_{GW} = -\frac{32}{5} \frac{G^{7/2}}{c^5} \frac{\mu^2 m_{12}^{5/2}}{a^{7/2}} \frac{1+7e^2/8}{(1-e^2)^2} \hat{\mathbf{L}}, \quad (4)$$

$$\left. \frac{d\mathbf{e}}{dt} \right|_{GW} = -\frac{304}{15} \frac{G^3}{c^5} \frac{\mu m_{12}^2}{a^4 (1-e^2)^{5/2}} \left( 1 + \frac{121}{304} e^2 \right) \mathbf{e}. \quad (5)$$

Here,  $m_{12} \equiv m_1 + m_2$ , and  $a$  is implicitly defined by  $\mathbf{L}$  and  $e$ . The last GR effect is precession of  $\vec{e}$ , which acts as

$$\left. \frac{d\mathbf{e}}{dt} \right|_{GR} = \frac{1}{t_{GR}} \hat{\mathbf{L}} \times \mathbf{e}, \quad (6)$$

$$\frac{1}{t_{GR}} \equiv \frac{3Gnm_{12}}{c^2 a (1-e^2)}. \quad (7)$$

Note that  $t_{GR}^{-1} \propto a^{-5/2}$ .

Given this system (from LML15 + LL18), we can then add the spin-orbit coupling term (from de Sitter precession), which is given in LL18 to be

$$\frac{d\hat{\mathbf{S}}}{dt} = \frac{1}{t_{SL}} \hat{\mathbf{L}} \times \hat{\mathbf{S}}, \quad (8)$$

$$\frac{1}{t_{SL}} \equiv \frac{3Gn(m_2 + \mu/3)}{2c^2a(1-e^2)}. \quad (9)$$

Note that  $\mu$  is the reduced mass of the inner binary. We can drop the back-reaction term since  $S \ll L$ . Thus,  $t_{SL}^{-1} \propto a^{-5/2}$  as well.

Finally, an adiabaticity parameter can be defined:

$$\mathcal{A} \equiv \left| \frac{\Omega_{SL}}{\Omega_L} \right|. \quad (10)$$

Here,  $\Omega_L \simeq \frac{3(1+4e^2)}{8t_{LK}\sqrt{1-e^2}} |\sin 2I|$  is an approximate rate of change of  $L$  during an LK cycle

It's natural to redimensionalize to the initial LK time such that

$$\frac{1}{t_{LK,0}} \equiv \left( \frac{a}{a_0} \right)^{3/2} \frac{1}{t_{LK}}, \quad (11)$$

since nothing else in  $t_{LK}$  is changing. The next natural timescale for gravitational waves is

$$\frac{1}{t_{GW}} \equiv \frac{G^3 \mu m_{12}^2}{c^5 a^4} \equiv \frac{1}{t_{GW,0}} \left( \frac{a_0}{a} \right)^4 \equiv \epsilon_{GW} \frac{1}{t_{LK,0}} \left( \frac{a_0}{a} \right)^4. \quad (12)$$

We can repeat the procedure for the GR precession term and the spin-orbit coupling terms:

$$\frac{1}{t_{GR}} = \epsilon_{GR} \frac{1}{t_{LK,0}} \left( \frac{a_0}{a} \right)^{5/2}, \quad (13)$$

$$\frac{1}{t_{SL}} = \epsilon_{SL} \frac{1}{t_{LK,0}} \left( \frac{a_0}{a} \right)^{5/2}. \quad (14)$$

Thus, finally, if we let  $\tau = t/t_{LK,0}$ , then we obtain full equations of motion (note that  $a_0 = 1$  below)

$$\begin{aligned} \frac{d\mathbf{L}}{d\tau} &= \left( \frac{a}{a_0} \right)^{3/2} \frac{3}{4} \sqrt{a} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2) - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2)] \\ &\quad - \epsilon_{GW} \left( \frac{a_0}{a} \right)^4 \frac{32}{5} \frac{1+7e^2/8}{(1-e^2)^{5/2}} \mathbf{L}, \end{aligned} \quad (15)$$

$$\begin{aligned} \frac{d\mathbf{e}}{d\tau} &= \left( \frac{a}{a_0} \right)^{3/2} \frac{3}{4} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2) + 2\mathbf{j} \times \mathbf{e} - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2)] \\ &\quad - \epsilon_{GW} \left( \frac{a_0}{a} \right)^4 \frac{304}{15} \frac{1}{(1-e^2)^{5/2}} \left( 1 + \frac{121}{304} e^2 \right) \mathbf{e} \\ &\quad + \epsilon_{GR} \left( \frac{a_0}{a} \right)^{5/2} \frac{1}{1-e^2} \hat{\mathbf{L}} \times \mathbf{e}, \end{aligned} \quad (16)$$

$$\frac{d\hat{\mathbf{S}}}{dt} = \epsilon_{SL} \left( \frac{a_0}{a} \right)^{5/2} \frac{1}{1-e^2} \hat{\mathbf{L}} \times \hat{\mathbf{S}}. \quad (17)$$

For reference, we note that  $a = |\mathbf{L}|^2 / (\mu^2 G m_{12} (1 - e^2))$ , while  $\mathbf{j} = \mathbf{L} / (\mu \sqrt{G m_{12} a})$ . To invert  $a(\mathbf{L})$  and  $\mathbf{J}(\mathbf{L})$  in this coordinate system where  $a_0 = 1$ , it is easiest to choose the angular momentum dimensions such that  $\mu \sqrt{G m_{12}} = 1$ , such that now

$$|\mathbf{L}(t=0)| \equiv \mu \sqrt{G m_{12} a_0 (1 - e_0^2)} = \sqrt{(1 - e_0^2)}, \quad (18)$$

$$a = \frac{|\mathbf{L}|^2}{1 - e^2}, \quad (19)$$

$$\mathbf{j} = \frac{\mathbf{L}}{\sqrt{a}} = \hat{\mathbf{L}} \sqrt{1 - e^2}. \quad (20)$$

Finally, the timescales are

$$t_{LK,0} = \frac{1}{n} \frac{m_{12}}{m_3} \left( \frac{a_2}{a(t=0)} \right)^3 (1 - e_2^2)^{3/2}, \quad (21)$$

$$\epsilon_{GW} \equiv \frac{t_{LK,0}}{t_{GW,0}} = \frac{1}{n} \frac{m_{12}}{m_3} \frac{a_2^3}{(a(t=0))^7} (1 - e_2^2)^{3/2} \frac{G^3 \mu m_{12}^2}{c^5}, \quad (22)$$

$$\epsilon_{GR} \equiv \frac{t_{LK,0}}{t_{GR,0}} = \frac{m_{12}}{m_3} \frac{a_2^3}{(a(t=0))^4} (1 - e_2^2)^{3/2} \frac{3G m_{12}}{c^2}, \quad (23)$$

$$\epsilon_{SL} \equiv \frac{t_{SL,0}}{t_{GR,0}} = \frac{m_{12}}{m_3} \frac{a_2^3}{(a(t=0))^4} (1 - e_2^2)^{3/2} \frac{3G (m_2 + \mu/3)}{2c^2}. \quad (24)$$

The adiabaticity parameter

$$\mathcal{A} \equiv \left| \frac{\Omega_{SL}}{\Omega_L} \right| = \frac{\epsilon_{SL}}{t_{LK,0}} \left( \frac{a_0}{a} \right)^{5/2} \frac{1}{1 - e^2} \left[ \frac{3(1 + 4e^2)}{8t_{LK,0} \sqrt{1 - e^2}} \left( \frac{a}{a_0} \right)^{3/2} |\sin 2I| \right]^{-1}, \quad (25)$$

(note that  $\Omega_L$  is a somewhat averaged sense, see LL18) can be evaluated in these units as

$$\mathcal{A} = \epsilon_{SL} \left( \frac{a_0}{a} \right)^4 \frac{1}{\sqrt{1 - e^2}} \frac{8}{3(1 + 4e^2) |\sin 2I|}. \quad (26)$$

Note also that the Hamiltonian is just

$$H = \Omega_{SL} \hat{\mathbf{L}} \cdot \hat{\mathbf{S}}, = \epsilon_{SL} \left( \frac{a_0}{a} \right)^{5/2} \frac{1}{1 - e^2} \hat{\mathbf{L}} \cdot \hat{\mathbf{S}}. \quad (27)$$

## 1.2 Maximum Eccentricity and Merger Time

Note that, since we are only evolving  $\mathbf{L}$  and  $\mathbf{e}$ , and not  $\mathbf{L}_2$  and  $\mathbf{e}_2$ , we are in the test mass approximation, under which we set  $\eta = 0$  in Bin's equations. As such, the maximum eccentricity satisfies (Eq 42 of LL18 with  $\eta \rightarrow 0$ )

$$\frac{3}{8} \frac{j_{\min}^2 - 1}{j_{\min}^2} [5 \cos I_0^2 - 3 j_{\min}^2] + \epsilon_{GR} \left( 1 - \frac{1}{j_{\min}} \right) = 0. \quad (28)$$

Note that  $\epsilon_{GR}$  is exactly as we defined above, incidentally, and that when GR is negligible, this reduces to the classic  $j_{\min} \equiv \sqrt{1 - e_{\max}^2} = \sqrt{\frac{5}{3} \cos^2 I_0}$ . Since  $\epsilon_{GR}$  is generally very small for most of the evolution, this generally reduces to the well known

$$e_{\max} = \sqrt{1 - \frac{5}{3} \cos^2 I_0}. \quad (29)$$

This only fails to saturate for extremely high eccentricities, so  $I_0 \rightarrow 90^\circ$ .

### 1.3 Attractor Behavior

Proposal: The reason the  $90^\circ$  attractor appears is that the initial  $\theta_{sb}$  is roughly stationary for  $\mathcal{A} \ll 1$  (only small kicks during each LK cycle, as long as the maximum eccentricity isn't too large), then as we enter the transadiabatic regime, the L-K cycles die down and we simply have conservation of adiabatic invariant.

The latter half of this follows the LL18 claim, where the requirement that  $\epsilon_{GR} \lesssim 9/4$  (GR precession of pericenter is slow enough that L-K survives) equates to  $\mathcal{A} \lesssim 3$ . The former half of this is somewhat tricky, but we can understand what is happening if we consider what is happening in the frame corotating with  $\Omega_{SL,e=0}$  about  $\hat{z}$ : every time that a LK cycle appears,  $\Omega_{SL}$  becomes much larger, and the axis of precession changes from  $\hat{z}$  to the location of  $\hat{L}$  very briefly. We can imagine this as a kick in this corotating frame (which is the right frame to consider for  $\mathcal{A} \ll 1$ ). In the limit that  $I$  does not change very much between L-K cycles, and the azimuthal angle of  $\hat{L}$  is roughly symmetric, the impulses roughly cancel out in the  $\theta_{sb}$  direction. In other words, after two LK cycles,  $\theta_{sb}$  does not change much in the corotating frame. This is indeed the picture that we obtain when we observe the plot.

As such, the hypothesis is that if  $\mathcal{A} \gtrsim 1$  is satisfied while the kicks are still *small*, then deviations about  $90^\circ$  cannot be very large, and adiabatic invariance tilts us right over. On the other hand, if the kicks have become *large*, then  $\theta_{sb}$  after any particular LK cycle is far from  $90^\circ$ , and this is frozen in during the adiabatic invariance phase. This explains the key observation that the initial  $\theta_{sb}$  eventually becomes the final  $\theta_{sl}$ , regardless of whether it is  $90^\circ$ . Furthermore, it explains why the kicks to  $\theta_{eff}$  become larger over time, but peak smaller for larger  $I_0$ .

The natural way to think about this is to consider the evolution of the trajectory in  $(a, e)$  space. There are two curves that can be drawn on here,  $\mathcal{A} \sim 1$  and  $|\Delta\theta_{sb}| \sim 1$  (the kick size), and then we can see which one gets crossed first. The hypothesis is that the first always gets crossed first, but if  $e_{\max}$  is too large, then the second gets crossed in the same LK cycle, and we get kicked far away from the starting  $\theta$ , and have this frozen into  $\theta_{sl}$ . We need to find out how to draw these boundaries in  $(a, e)$  space. Drawing  $\mathcal{A}$  is very easy, since we have the explicit formula for it.

To get the kick size, we have to integrate one of the LK peaks. This is easiest done by considering the evolution of the  $\delta e \equiv 1 - e$  variable by dotting  $\vec{e}$  into  $\frac{d\vec{e}}{dt}$ , such that

$$2e \frac{de}{dt} = \frac{d(\vec{e} \cdot \vec{e})}{dt} = 2\vec{e} \cdot \frac{d\vec{e}}{dt}, \quad (30)$$

$$= -\frac{15}{2t_{LK}} (\mathbf{e} \cdot \hat{n}_2)(\hat{n}_2 \cdot (\mathbf{e} \times \mathbf{j})), \quad (31)$$

$$\lesssim \pm \frac{15}{2t_{LK}} e^2 \sqrt{1 - e^2}, \quad (32)$$

$$\frac{de}{dt} \sim -\frac{15}{4t_{LK}} e \sqrt{1 - e^2}, \quad (33)$$

$$\frac{d(\delta e)}{dt} \sim \frac{15}{4t_{LK}} \sqrt{2\delta e}, \quad (34)$$

$$\delta e(t) \sim \left( \frac{15t}{4\sqrt{2}t_{LK}} \right)^2. \quad (35)$$

The finding of a power law/quadratic seems in accordance w/ my simulations, though I have to plot

$\delta e - \delta e_{\min}$ . Then, we can simply integrate

$$\Delta\theta_{sb} \sim \oint_{LK} \Omega_{SL} dt, \quad (36)$$

$$\sim \frac{\epsilon_{SL}}{2} \left(\frac{a_0}{a}\right)^{5/2} \oint_{LK} \frac{1}{\delta e} dt, \quad (37)$$

$$\sim \frac{\epsilon_{SL}}{2} \left(\frac{a_0}{a}\right)^{5/2} \oint_{LK} \frac{1}{\delta e_{\min} + \left(\frac{15}{4\sqrt{2}t_{LK}}\right)^2 t^2} dt, \quad (38)$$

$$\sim \frac{\epsilon_{SL}}{2\delta e_{\min}} \left(\frac{a_0}{a}\right)^{5/2} \pi \frac{4t_{LK}\sqrt{2\delta e_{\min}}}{15}, \quad (39)$$

$$\sim \frac{\epsilon_{SL}}{\sqrt{2\delta e_{\min}}} \frac{a_0}{a} \pi \frac{4}{15}. \quad (40)$$

In the last few steps, we've just taken the bounds of integration to be  $t \in [-\infty, \infty]$  for simplicity (they contribute negligibly), and used  $t_{LK} = (a/a_0)^{3/2}$  since  $t_{LK,0} = 0$ .

If we now explicitly write down the criteria where  $\mathcal{A} \sim 1$  and  $\Delta\theta_{sb} \sim 1$  in the  $(a, e)$  plane, then we obtain

$$a_{c,\theta} \sim \frac{\epsilon_{SL}}{\sqrt{2\delta e_{\min}}} \frac{4\pi}{15}, \quad (41)$$

$$a_{c,\mathcal{A}} \sim \left[ \epsilon_{SL} \frac{8/3}{\sqrt{1 - e_{\min}^2} (1 + 4e_{\min}^2) |\sin 2I|} \right]^{1/4}. \quad (42)$$

The key difference between the two is that kicks occur at  $e_{\max}$  or  $\delta e_{\min}$ , while the adiabaticity parameter is moreso evaluated at  $e_{\min}$ .

**Update:** This cannot be the correct mechanism since it would generate symmetric scatter of  $\theta_{sl}$  about  $\theta_{sb,0}$ , which is not the case (see Fig 19 of LL18). Instead, it must really be how quickly the axis of precession of  $\frac{d\hat{\mathbf{S}}}{dt}$  moves compared to the precession frequency, or indeed  $|\Omega_{eff}|$  as compared to  $\frac{d\hat{\Omega}_{eff}}{dt}$ .

## 1.4 More analysis on LL18's proposal

Note that, since  $\theta_{sb}$  during the LK oscillations will receive a sequence of kicks, it randomizes the ordering a bit, so exact conservation of  $\theta_{sb,i}$  to  $\theta_{sl,f}$  is not maintained (i.e. the ordering can change somewhat).

But ultimately, it must boil down indeed to comparison of the change in precession axis vs the precession frequency. One of the key difficulties in this conclusion in LL18 is neglect of nutation in Equations 64 and 65. However, in the transadiabatic regime, the LK cycles are of small amplitude ( $1 - e$  typically at least  $\lesssim 0.1$ , often  $\lesssim 0.01$  throughout the cycles) and are fast, and as a result  $I$  is to good approximation constant and nutation can likely be neglected; at worst an average value of  $\mathbf{L}$  can be used. The final spread in  $\theta_{sl,f}$  probably comes from the spread in  $\theta_{sb,i}$  upon exiting the nonadiabatic regime, due to the kicks during the LK cycles. **NB:** Another way to argue that the fast nutation can be ignored is if  $\Delta I \ll \theta_{\text{eff},S}$ , since then the spin vector just precesses around a fuzzy vector, which isn't a huge deal. If the precession frequencies are equal, it's possible to hit an SHO-like resonance, which should probably be dealt with TODO.

Let's suppose this is the case for the time being, where  $e$ ,  $I$ , and  $a$  are all approximately slowly varying going into the transadiabatic regime. Then let's go to the co-rotating frame with  $\mathbf{L}$  (fix this in the  $\hat{x}, \hat{z}$  plane) and look at the evolution of the components of  $\mathbf{\Omega}_{\text{eff}}$ :

$$\mathbf{\Omega}_{\text{eff}} = \Omega_{SL} (\sin I \hat{x} + \cos I \hat{z}) + \Omega_{pl} \hat{z}, \quad (43)$$

$$\hat{\mathbf{\Omega}}_{\text{eff}} \cdot \hat{z} = \frac{\Omega_{SL} \cos I + \Omega_{pl}}{\sqrt{\Omega_{SL}^2 \sin^2 I + (\Omega_{SL} \cos I + \Omega_{pl})^2}}. \quad (44)$$

Then, we just have to compare  $\frac{d \arccos \hat{\Omega}_{\text{eff},z}}{dt}$  to  $\Omega_{\text{eff}}$  the magnitude, and this tells us whether  $\hat{S}$  can track  $\mathbf{\Omega}_{\text{eff}}$  as it moves. This tracks the polar angle, and the  $z$  component doesn't have a singularity during the evolution and is preferable (compared to the  $x$  component). If all quantities are slowly varying (at roughly constant speeds), the characteristic speed at which the polar angle varies occurs when it is  $\sim 90^\circ$ , or when  $\Omega_{\text{eff},z} \approx 0$ , so we can simplify the expression a bit

$$\frac{d \arccos \hat{\Omega}_{\text{eff},z}}{dt} \lesssim \frac{d}{dt} \left( \frac{\Omega_{SL} \cos I + \Omega_{pl}}{\Omega_{SL} \sin I} \right) \sim \frac{1}{\sin I} \frac{d(\mathcal{A}^{-1})}{dt} \quad (45)$$

In summary, the picture is as follows:

- Starting from some initial  $\theta_{sb,0}$ , there are some random kicks (which cancel slightly better than a random walk, i.e. the variance does not seem to grow), we exit the nonadiabatic regime with some random value  $\in \theta_{sb,0} \pm \Delta \theta_{sb}$ .
- Under the influences of  $\epsilon_{GW}$  on  $e_{\text{max}}$  and  $\epsilon_{GR}$  on  $e_{\text{min}}$ , the trajectory flows towards a single point in  $(a, e)$  space. Note that  $I$  should be fixed by approximate conservation of the Kozai constant, since the GW effect is much weaker than the GR effect, and the GR effect preserves the Kozai constant.
- If the system hasn't exited the Kozai regime or merged at this point, it will evolve with small LK oscillations about GR decay of  $e$  and  $a$ , coupled to convergence in  $I$ . As GR acts, this fuzz gets smaller and smaller amplitude until GR breaks the LK resonance.

During this fuzzy phase, so long as  $\Omega_{\text{eff}} \gtrsim \frac{d(\mathcal{A})^{-1}}{dt} / \sin I$ , then  $\theta_{sb}$  gets sent to  $\theta_{sl,f}$ . The fuzz timescale is so short that it can be averaged over (the spin can't see it), so we should just have to consider the GR decay timescale when making this comparison.

- Regardless of whether the transadiabatic phase conserves the adiabatic invariant  $\theta_{\text{eff}}$ , the final value is conserved once LK entirely disappears and it's just slow GR decay (which will evolve  $\Omega_{\text{eff}}$  slightly, but more obviously slowly).

## 1.5 Timescales for My Picture

**NB:** we are in the circulating regime of the L-K mechanism!

We now make some comments on the dynamics in each of these regimes:

- During the initial pure-LK phase, there are small perturbations to  $\theta_{sb}$  as we derived above.

But furthermore, we can estimate the characteristic number of LK cycles by observing that the decay in the range of  $\omega$  oscillation is what drives  $e_{\text{min}}$  to increase over time. We can integrate

one Kozai cycle

$$\Delta\omega = \oint_{LK} \frac{3Gnm_{12}e}{c^2a(1-e^2)} dt, \quad (46)$$

$$\approx \frac{Gnm_{12}e}{2c^2a} \int_{-\infty}^{\infty} \frac{1}{\delta e_{\min} + \left(\frac{15t}{4\sqrt{2}t_{LK}}\right)^2} dt, \quad (47)$$

$$\approx \frac{3Gnm_{12}4\pi t_{LK}}{c^2a\sqrt{2\delta e_{\min}}}. \quad (48)$$

It's likely we can replace  $\sqrt{2\delta e_{\min}} \rightarrow \sqrt{1-e_{\max}^2}$ .

We should be able to determine the number of Kozai cycles before coalescence by computing  $\frac{\partial H}{\partial \omega}$  at  $e_{\max}$ , which I haven't done.

If we ignore GW effects, the final state for this phase is where  $e \approx e_{\max}, I \approx I_{\min}$ . There are small corrections due to (i) GW decay near the high- $e$  phases; we can estimate the former, since we also know the number of high- $e$  cycles, but it may not be very important.

- During the fuzz phase, let's assert that  $\omega, I$  make small amplitude oscillations about mean values that evolve slowly under GW emission (which also affects  $a$ ): note that  $I$  is affected because GW emission is approximately adiabatic compared to the LK timescale. What sets the frequency and amplitude of these oscillations?

**Gave up:** some online references seem to suggest that oscillations get to order  $\sim t_{LK}/6$  as we have defined it<sup>1</sup>, while in our simulations, each LK cycle actually is much longer than this initially, so that gives us a decent idea of the timescale of the “fuzz.” **Edit:** It's probably even faster, since this is the librating timescale, so let's just assume the fuzz is very short scale. **Edit 2:** It is bound from below by  $\Omega_{GR}$ , since that's one component of  $\dot{\omega}$ , and it must be at least as fast.

Looking at the phase portrait, it's more clear that the GR precession will eventually just send entire trajectory to be roughly constant at  $e_{\max} \rightarrow 1$ . It's not clear that the amplitude of these oscillations ever saturates, but it's obvious that they are small and continue to decrease. One way to see that this is the case is to consider the  $H(\omega, x)$  surface, where we drop constant of proportionality

$$H \propto (2 + 3e^2)(3\cos^2 I - 1) + 15e^2 \sin^2 I \cos 2\omega, \quad (49)$$

and  $I$  is implicitly defined by conservation of the Kozai constant  $K = \sqrt{1-e^2} \cos I$ . We can see that along the separatrix,  $H = -2$ , if we give a kick at the location of maximum eccentricity ( $\sin^2 I = 2/5, e = 1, \omega = \pi/2$ ), the change in  $H$  is quadratic like

$$\delta H = \frac{1}{2} \frac{\partial^2 H}{\partial \omega^2} (\delta \omega)^2, \quad (50)$$

where  $\delta \omega \sim (1 - e_{\max}^2)^{-1/2}$  was an earlier result we showed. The sign of this term is negative, so  $H$  is being driven towards oscillating at large  $e$  with small amplitude.

In any case, the fuzz decreases in amplitude over time and oscillates faster and faster, probably  $\ll t_{LK}$  (indeed so, according to my plots).

<sup>1</sup><https://arxiv.org/pdf/1504.05957.pdf>

- As we evolve through the fuzz, we want to understand whether  $\theta_{\text{eff},S}$  evolves adiabatically. We need to evaluate the precession frequency and the rate of change of the precession axis, but for this we need expressions for  $\dot{e}, \dot{I}, \dot{a}$  through the fuzz. Based on the final observation that  $\dot{\omega}_{GR}$  doesn't affect the mean eccentricity, we can assert that  $\dot{e} = \dot{e}_{GW}$ ,  $\dot{a} = \dot{a}_{GW}$ , while  $I$  is constrained implicitly by conservation of the Kozai constant (so long as Kozai still is active). Thus, to order of magnitude,  $\dot{\Omega}_{\text{eff}} \sim \dot{\Omega}_{GW}$  while  $\dot{\Omega}_{\text{eff}} \sim \dot{\Omega}_{GR}$ , and since  $\Omega_{GW} \propto 1/(a^4 x^{7/2})$  while  $\Omega_{GR} \propto 1/(a^{5/2} x)$ , it's clear that for sufficiently large eccentricities exiting the fuzz regime that  $\hat{S}$  will not keep up with  $\hat{\Omega}_{\text{eff},S}$ .

If so, what is the predicted  $\theta_{sl,f}$ ? Well, suppose that  $\hat{L}$  ends up on the ring with uniform  $I$  (probably...), and take the limit where  $\hat{S}$  is not able to respond at all, then  $\theta_{sl,f} \in [I - \theta_{sb,i}, 2\pi - I - \theta_{sb,i}]$  and is roughly centered on  $\pi - \theta_{sb,i}$ .

**NB:** Above, we said  $\Omega_{\text{eff}} \sim \Omega_{GR}$  based on saying that  $\hat{L}$  precesses around  $\hat{L}_{\text{out}}$  with  $\dot{\omega}_{GR}$ , but of course, if evolution is sufficiently abrupt, we should really use  $\Omega_{\text{eff}} \sim \Omega_{\text{pl}}$ , and if evolution is abrupt this is  $\ll \Omega_{GR}$ , further contributing to making the nonadiabatic criterion easy to satisfy.

- Note that there is one more way that this picture can break down, as we saw examples of in Bin's paper: we can get trapped in the LK resonance such that  $\omega$  librates instead of circulating. This is not in general easy to do, since we start with  $e \neq 0, \omega = 0$ . Furthermore, to linear order,  $\oint \frac{\partial H}{\partial \omega} \frac{d\omega}{dt} dt = 0$  along the separatrix (it cancels during the increasing  $e$  and decreasing  $e$  phases). But we can imagine that if  $\omega_{GR}$  is so strong, then  $\dot{\omega}$  will drive the Kozai cycle inside the resonance during just the increasing  $e$  phase alone, and takes a very different route back to low  $e$  such that it is captured. That this is a nonlinear effect in  $\delta\omega_{GR}$  might be important, since otherwise the resonance capture dynamics would only depend on the initial condition: the separatrix would open a gap like in the CS problem and for arbitrarily weak  $\omega_{GR}$  we could still experience separatrix capture, which is obviously not the case?

The advantage of invoking this mechanism is twofold: (i) if we look at Fig. 19 of LL18, it's clear that the distribution of  $\theta_{sl,f}$  is roughly symmetric for a stronger companion (faster LK cycles), but becomes markedly asymmetric for a weaker companion (LK is weak). The violation of adiabaticity proposed above is generally expected to generate a  $\theta_{sl,f}$  distribution symmetric about its mean. But capturing  $\hat{L}$  into the  $\omega = \pi/2$  resonance means  $\hat{S}$  precesses *towards* it as it becomes dominant, meaning that  $\theta_{sl,f} \lesssim 90^\circ$  is enforced. (ii), the above mechanism does not depend on the properties of the perturber or of the Kozai timescale, so there should be no change in distribution of  $\theta_{sl,f}$  as a function of  $a_{\text{out}}$ . This resonance capture mechanism provides a way for the outcome to be sensitive to the perturber properties.

Edit: Looks like I got  $\Omega, \omega$  confused, and most of the above is either wrong or not new.

## 2 Fresh Start

**NB:** I think these orbital elements Kozai actually give much slower inspirals. It could be because my atol/rtol params were too loose when I was doing the vector simulations, so we should prefer the 4sims line of results, which qualitatively seem to agree with Bin's.

### 2.1 Useful Kozai Results

I have a bunch of formulas that I need to write down before I forget them, so I'll do that here. We have begun analyzing the EOM (at quadrupolar order) in Keplerian orbital elements, so I'll reproduce

them here

$$\frac{da}{dt} = -\frac{64}{5} \frac{a}{t_{GW,0}} \frac{1}{(1-e^2)^{7/2}} \left( 1 + \frac{73}{24}e^2 + \frac{37}{96}e^4 \right), \quad (51)$$

$$\frac{de}{dt} = \frac{15}{8t_{LK}} e \sqrt{1-e^2} \sin 2\omega \sin^2 I - \frac{304}{15} \frac{e}{t_{GW,0}} \frac{1}{(1-e^2)^{5/2}} \left( 1 + \frac{121}{304}e^2 \right), \quad (52)$$

$$\frac{d\Omega}{dt} = \frac{3}{4t_{LK}} \frac{\cos I (5e^2 \cos^2 \omega - 4e^2 - 1)}{\sqrt{1-e^2}}, \quad (53)$$

$$\frac{dI}{dt} = -\frac{15}{16t_{LK}} \frac{e^2 \sin 2\omega \sin 2I}{\sqrt{1-e^2}}, \quad (54)$$

$$\frac{d\omega}{dt} = \frac{3}{4t_{LK}} \frac{2(1-e^2) + 5\sin^2 \omega (e^2 - \sin^2 I)}{\sqrt{1-e^2}} + \frac{\Omega_{GR,0}}{1-e^2}, \quad (55)$$

$$\frac{d\hat{\mathbf{S}}}{dt} = \frac{\Omega_{SL,0}}{1-e^2} \hat{\mathbf{L}} \times \hat{\mathbf{S}}. \quad (56)$$

Here, we have defined

$$t_{LK}^{-1} = n \left( \frac{m_3}{m_{12}} \right) \left( \frac{a}{a_3} \right)^3, \quad (57)$$

$$t_{GW,0}^{-1} = \frac{G^3 \mu m_{12}^2}{c^5 a^4}, \quad (58)$$

$$\Omega_{GR,0} = \frac{3Gn m_{12}}{c^2 a}, \quad (59)$$

$$\Omega_{SL,0} = \frac{3Gn (m_2 + \mu/3)}{2c^2 a}. \quad (60)$$

and  $n = \sqrt{Gm_{12}/a^3}$  is the mean motion of the inner binary. We define/recall the following:

- $K = \sqrt{1-e^2} \cos I$  is conserved, and we will sometimes write  $x = 1 - e^2$ .
- Kozai eccentricity excursions occur at  $\omega = \pi/2, 3\pi/2$ .
- If we ever need this, Natalia's paper gives "closed" forms for the eccentricity evolution

$$x = x_0 + (x_1 - x_0) \text{cn}^2(\theta, k^2), \quad (61)$$

$$\theta = \frac{K}{\pi} (n_e t + \pi), \quad (62)$$

$$n_e = \frac{6\pi\sqrt{6}}{8Kt_{LK}} \sqrt{x_2 - x_1}, \quad (63)$$

$$k^2 = \frac{x_0 - x_1}{x_2 - x_1}. \quad (64)$$

Here,  $x_0$  and  $x_1$  are the maximum/minimum  $x$  respectively (corresponding to min/max eccentricity), and  $x_2$  is the other root to the quadratic ( $x_1$  is one of them).

$$x^2 - \frac{1}{3}(5 + 5K - 2x_0)x + \frac{5K}{3} = 0. \quad (65)$$

Note that this implies  $x_1 + x_2 = \frac{5+5K-2x_0}{3}$ .

- In terms of this  $x$  parameter, the LK components of the EOM take on particularly simple form

$$\dot{\Omega} = \frac{3\sqrt{K}}{4t_{LK}} \left( 1 - 2 \frac{x_0 - h}{x - h} \right), \quad (66)$$

$$\dot{I} = \frac{\dot{x} \cos I}{2x \sin I}. \quad (67)$$

It is not so hard to solve for the Kozai resonance location in the absence of GW radiation; we know this occurs at  $\omega = \pi/2$ , which forces  $\dot{e} = \dot{I} = 0$ , then we set  $\dot{\omega} = 0$  and find

$$\frac{d\omega}{dt} = \frac{3}{4t_{LK}} \frac{2(1-e^2) + 5(e^2 - \sin^2 I)}{\sqrt{1-e^2}} + \Omega_{GR}, \quad (68)$$

$$0 = \frac{\Omega_{GR} \sqrt{1-e^2} 4t_{LK}}{3} + 2(1-e^2) - 5(1 - \cos^2 I - e^2), \quad (69)$$

$$5 \cos^2 I = 3(1-e^2) + \mathcal{O}(\Omega_{GR}). \quad (70)$$

Then, given some  $K$ , which is conserved even with GR precession, we know  $(I, e)$  the Kozai resonance. To obtain the  $\mathcal{O}(\Omega_{GR})$  correction, we have to solve a quadratic, which yields

$$\sqrt{1-e^2} = \frac{5 \cos^2 I}{6} \left( 2 + \sqrt{1 + \frac{16\Omega_{GR} t_{LK}}{25 \cos^4 I}} \right). \quad (71)$$

If  $\Omega_{GR}$  is strong, the equilibrium condition drives  $\cos^2 I \rightarrow 0$ , and simplifying in this limit we get the familiar condition  $\Omega_{GR} t_{LK} \leq 9/4$  for the Kozai resonance itself to exist (of course, the separatrix about which trajectories librate will begin shrinking much earlier).

We can use this to understand what  $\mathcal{A}$  looks like when Kozai disappears. Assuming  $m_1 = m_2$ , we can find  $\Omega_{SL} = \Omega_{GR} \frac{7}{24}$ , and so when Kozai dies we obtain constraints

$$\Omega_{SL} t_{LK} = \frac{21}{32}, \quad (72)$$

$$\mathcal{A} \simeq \left| \frac{\Omega_{SL}}{\dot{\Omega}} \right| = \frac{7}{8} \frac{\sqrt{1-e^2}}{\cos I (4e^2 + 1)}. \quad (73)$$

If we plug in the values near the Kozai equilibrium when it disappears, we find rough scaling

$$\mathcal{A} \simeq \frac{7}{8(1+4e^2) \cos I}. \quad (74)$$

Thus, indeed, typically  $\mathcal{A} \sim 1$  when Kozai dies.

Finally, it bears noting that

$$\mathcal{A} = \mathcal{A}_0 \frac{1}{(1+4e^2) \sqrt{1-e^2} |\sin 2I|}, \quad (75)$$

$$= \mathcal{A}_0 \frac{1}{2(1+4e^2) K \sin I}. \quad (76)$$

Thus, over the course of a Kozai cycle, where  $\sin I \in [\sqrt{2/5}, 1]$ , and  $e \in [0, 1]$ , the adiabaticity does not actually change very much, unless  $\mathcal{A}_0 \propto a^{-4}$  changes significantly due to  $\dot{a}_{GW}$ .

## 2.2 Hamiltonian Approach 1: Natalia Style

We go to the frame where  $\hat{\mathbf{L}}$  is stationary. The rotation vector is the same as in SL15, and we obtain Hamiltonian ( $\hat{\mathbf{L}}_o$  is the outer angular momentum, is constant in nonrotating frame)

$$H = \Omega_{SL} \cos \theta - \mathbf{R} \cdot \hat{\mathbf{S}}, \quad (77)$$

$$\mathbf{R} \equiv \left( \dot{\Omega} \hat{\mathbf{L}}_o + \dot{I} \left( \frac{\hat{\mathbf{L}}_o \times \hat{\mathbf{L}}}{\sin I} \right) \right). \quad (78)$$

If we break down all the vectors into component form, such that  $\hat{\mathbf{L}} = \hat{\mathbf{z}}$ ,  $\hat{\mathbf{L}}_o = -\sin I \hat{\mathbf{x}} + \cos I \hat{\mathbf{z}}$ , then we obtain

$$H = \Omega_{SL} \cos \theta - \dot{\Omega} (-\sin I \sin \theta \cos \phi + \cos I \cos \theta) + \dot{I} \sin \theta \sin \phi. \quad (79)$$

Note ICs  $\theta = 0$ ,  $\phi = 0$ ,  $I = 90^\circ$ . The EOM are

$$\dot{\phi} = \frac{\partial H}{\partial \cos \theta} = \Omega_{SL} - \dot{\Omega} \cos I - \cot \theta (\dot{\Omega} \sin I \cos \phi - \dot{I} \sin \phi), \quad (80)$$

$$\frac{d(\cos \theta)}{dt} = -\frac{\partial H}{\partial \phi} = -\dot{\Omega} \sin I \sin \theta \sin \phi + \dot{I} \sin \theta \cos \phi, \quad (81)$$

$$\frac{d\theta}{dt} = -\frac{1}{\sin \theta} \frac{d(\cos \theta)}{dt} = \dot{\Omega} \sin I \sin \phi - \dot{I} \cos \phi. \quad (82)$$

If we assume  $\Omega_{SL} \ll \dot{\Omega}, \dot{I}$  initially, even during LK peaks (which is true by our experience), then we can imagine breaking down the trajectory of  $\hat{\mathbf{S}}$  into a zeroth order precession about  $\mathbf{R}$  (which is very complicated, since  $\mathbf{R}$  is both moving and changing in magnitude) and a leading order perturbation due to  $\Omega_{SL}$ . The perturbation Hamiltonian is then given

$$H^{(1)} = \Omega_{SL}(t) [\cos \theta](t). \quad (83)$$

If we're brave like Natalia, we would expand  $\cos \theta(t)$  in Fourier components, and  $\Omega_{SL}(t)$  in Fourier components, but there is clearly no chance for a resonance here since there is no  $\phi$  dependence, so the level curves of this Hamiltonian are azimuthally symmetric and there can be no resonance.

Conversely, if we're in the other regime  $\Omega_{SL} \gg \dot{\Omega}, \dot{I}$ , we must be in the regime where Kozai cycles have died out, which implies  $\dot{I} = 0$ . Here, the Hamiltonian is much more similar to Natalia's problem. Let's consider that  $\theta = \theta_0$  and  $\phi = \Omega_{SL} t$ , then the perturbing Hamiltonian is

$$H^{(1)} = \dot{\Omega} (-\sin I \sin \theta_0 \cos \phi + \cos I \cos \theta_0). \quad (84)$$

Again, there is no resonance condition since there is only one  $\phi$  dependent term, and we really need two so we can get a form  $\cos(\phi - Mt)$  like Natalia's problem. Thus, there are no resonances to investigate here.

We can identify the key reasons that we don't have a similar problem:

- LK is not a perturbation for us (compared to  $\hat{\mathbf{S}} \cdot \hat{\mathbf{L}}$  dynamics), it is significantly dominant. This corresponds to the  $\mathcal{A} \ll 1$  regime of SL15. They obtain a neat bifurcation due to separatrix crossing, which is not observed in our LK simulations, so this cannot in spirit be a similar mechanism.
- SL15 focuses on adiabatically changing  $\mathcal{A}$  and seeing how it encounters resonances. In our problem, nothing nontrivial can occur if  $\mathcal{A}$  changes slowly.
- Our Hamiltonian takes on form  $H = (\Omega_{SL} - \mathbf{R}) \cdot \hat{\mathbf{S}}$ . This will never have any resonances since it's perfectly linear; anything that looks nonlinear is a pure consequence of coordinates (e.g. multiplication of  $\theta$  and  $\phi$  terms).

### 2.3 Hamiltonian 2: Rotating Style

Why is the previous Hamiltonian hard to use? Well, since there are no resonances, and  $H$  is linear in  $\hat{\mathbf{S}}$ , it makes much more sense to just analyze the EOM. As such, it's better to just find the right set of rotations such that we have a convenient coordinate. LL18 proposed this  $\theta_{\text{S,eff}}$ , and I think this is the right idea, but it can be expounded on.

Let's consider the following: we clearly want to rotate by at least  $\dot{\Omega}\hat{\mathbf{L}}_o$ , so that  $\mathbf{L}$  does not precess any more, but it still nutates ( $\dot{I}$ ) about fixed  $\hat{\mathbf{L}}_o = \hat{\mathbf{z}}$ . Let's first write down the Hamiltonian and the EOM for this case:

$$H = \Omega_{SL}\hat{\mathbf{S}} \cdot \hat{\mathbf{L}} - \dot{\Omega}\hat{\mathbf{L}}_o \cdot \hat{\mathbf{S}}, \quad (85)$$

$$= \Omega_{SL}(\sin I \sin \theta \cos \phi + \cos I \cos \theta) - \dot{\Omega} \cos \theta, \quad (86)$$

$$\frac{d \cos \theta}{dt} = -\frac{\partial H}{\partial \phi} = -\Omega_{SL} \sin I \sin \theta \sin \phi, \quad (87)$$

$$\frac{d\theta}{dt} = \Omega_{SL} \sin I \sin \phi, \quad (88)$$

$$\frac{d\phi}{dt} = \frac{\partial H}{\partial \cos \theta} = -\Omega_{SL} \sin I \cot \theta \cos \phi + \Omega_{SL} \cos I - \dot{\Omega}. \quad (89)$$

This is an even stupider example than the previous section, since the desired final angle  $\theta_{sl,f}$  is almost impossible to measure, and writing down  $\theta_{sl,f}$  would give huge excursions early in the evolution due to  $\dot{I}$  (we've seen this plot before, in LL18). But similarly, the EOM from the previous section is also very difficult to use, since it's very unclear how  $\theta = \theta_{sl}$  evolves through the Kozai phase; with the benefit of hindsight, we know that this  $\theta$  equation is just along a great circle normal to  $\mathbf{R}$ , but it's hard to say anything quantitative other than "this angle gets frozen by conservation of adiabatic invariant."

Instead, let's consider applying an arbitrary rotation in the  $\hat{\mathbf{y}}$  direction for the time being, let's call it  $\mathbf{R} = \dot{I}_o \hat{\mathbf{y}}$ ; taking this to equal either 0 or  $I$  equates to taking  $\hat{\mathbf{L}}_o$  or  $\hat{\mathbf{L}}$  as  $\hat{\mathbf{z}}$  respectively. We can write down this Hamiltonian, calling  $I_L = I - I_o$  (these have interpretation of  $\cos I_L = \hat{\mathbf{L}} \cdot \hat{\mathbf{z}}$  and  $\cos I_o = \hat{\mathbf{L}}_o \cdot \hat{\mathbf{z}}$  respectively)

$$H = \Omega_{SL}\hat{\mathbf{S}} \cdot \hat{\mathbf{L}} - \dot{\mathbf{R}} \cdot \hat{\mathbf{S}}, \quad (90)$$

$$= \Omega_{SL}(\sin I_L \sin \theta \cos \phi + \cos I_L \cos \theta) - \dot{\Omega}(-\sin I_o \sin \theta \cos \phi + \cos I_o \cos \theta) + \dot{I}_o \sin \theta \sin \phi, \quad (91)$$

$$\frac{d \cos \theta}{dt} = -(\Omega_{SL} \sin I_L + \dot{\Omega} \sin I_o)(-\sin \theta \sin \phi) - \dot{I}_o \sin \theta \cos \phi, \quad (92)$$

$$\frac{d\theta}{dt} = -(\Omega_{SL} \sin I_L - \dot{\Omega} \sin I_o) \sin \phi + \dot{I}_o \cos \phi, \quad (93)$$

$$\frac{d\phi}{dt} = -\cot \theta (\Omega_{SL} \sin I_L \cos \phi + \dot{\Omega} \sin I_o \cos \phi - \dot{I}_o \sin \phi) + (\Omega_{SL} \cos I_L - \dot{\Omega} \cos I_o). \quad (94)$$

Immediately, we can see both of the terms that made the above equations hard to work with: both  $\Omega_{SL} \sin I_L$  and  $\dot{\Omega} \sin I_o$  become large at some point or another, making it hard to consider the effect on the final  $\theta$ . But if we choose some  $\dot{I}_o$  such that  $\theta(t=0) = \theta_{sb}$  while  $\theta(t=\infty) = \theta_{sl}$ , then the EOM is easy to analyze in both regimes.

Instead, the obvious thing to do is as follows: choose  $\dot{I}_o$  such that  $\Omega_{SL} \sin I_L = \dot{\Omega} \sin I_o$ , also satisfying  $I_L + I_o = I$ . This ensures that the two terms  $\Omega_{SL}$  and  $\dot{\Omega}$  are almost always small, while  $\dot{I}_o$  is generally symmetric per cycle. On the other hand,  $\phi \approx \max(\Omega_{SL}, \dot{\Omega})$ .

This immediately lets us read off one adiabaticity criterion: if  $\cos \phi$  doesn't sweep through  $2\pi$  much faster than it takes  $\dot{I}_o$  to accumulate, then  $\theta$  will receive a kick. Another adiabaticity criterion

is obvious: the number of times we cross  $\Omega_{SL} \simeq \dot{\Omega}$  will yield a substantially larger kick than usual, since  $\Omega_{SL}, \dot{\Omega} \gg \dot{I}_o$ .

Let's be a bit more quantitative and write down this  $\dot{I}_o$  rotation. It must satisfy (recall  $I_L = I - I_o$ )

$$\Omega_{SL} \sin I_L = \dot{\Omega} \sin I_o, \quad (95)$$

$$\dot{\Omega}_{SL} \sin I_L + \Omega_{SL} \cos I_L (\dot{I} - \dot{I}_o) = \ddot{\Omega} \sin I_o + \dot{\Omega} \cos I_o \dot{I}_o, \quad (96)$$

$$\dot{\Omega}_{SL} \sin I_L - \ddot{\Omega} \sin I_o + \Omega_{SL} \cos I_L \dot{I} = \dot{I}_o (\dot{\Omega} \cos I_o + \Omega_{SL} \cos I_L), \quad (97)$$

$$\dot{I}_o = \frac{\dot{\Omega}_{SL} \sin I_L - \ddot{\Omega} \sin I_o + \Omega_{SL} \cos I_L \dot{I}}{\dot{\Omega} \cos I_o + \Omega_{SL} \cos I_L} \quad (98)$$

This is an absolute mess, but does it hold up?

- Well, if we are in the  $\dot{\Omega} \sim \dot{I} \gg \Omega_{SL}$  limit, then  $I_o \approx 0$ , and things simplify to

$$\frac{\dot{I}_o}{\dot{I}} \approx \frac{\dot{\Omega}_{SL} \sin I / \dot{I} + \Omega_{SL} \cos I}{\dot{\Omega}} \ll 1, \quad (99)$$

since all time derivatives are the same,  $\sim 1/t_{LK}$ . This is correct, since the rotation should basically not be acting in this limit.

- And in the other limit,  $\dot{\Omega} \sim \dot{I} \ll \Omega_{SL}$  limit, then  $I_l \approx 0$  and we have

$$\frac{\dot{I}_o}{\dot{I}} \approx \frac{-\ddot{\Omega} \sin I_o / \dot{I} + \dot{I} \Omega_{SL} \cos I}{\Omega_{SL} \cos I} \approx 1. \quad (100)$$

This is also correct, since in this limit we should have to rotate by  $\dot{I}$ .

Thus, it seems like we have the correct expression, as ugly as it is. In fact, numerically, this turns out to be exactly  $\Omega_{\text{eff}}$ , which shouldn't be a huge surprise, since that's exactly our definition.

## A j Equations

We define vectors

$$\mathbf{j} = \sqrt{1 - e^2} \hat{n}, \quad (101)$$

$$\mathbf{e} = e \hat{u}. \quad (102)$$

Here,  $\mathbf{j}$  is the dimensionless angular momentum vector and  $\mathbf{e}$  is the eccentricity vector; see LML15 for precise definitions. Note that  $\mathbf{j} \cdot \mathbf{e} = 0$ ,  $j^2 + e^2 = 1$ . Then, the EOM for the inner and outer vectors satisfy to quadrupolar order

$$\frac{d\mathbf{j}}{dt} = \frac{3}{4t_{LK}} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2) - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2)], \quad (103)$$

$$\frac{d\mathbf{e}}{dt} = \frac{3}{4t_{LK}} [(\mathbf{j} \cdot \hat{n}_2)(\mathbf{e} \times \hat{n}_2) + 2\mathbf{j} \times \mathbf{e} - 5(\mathbf{e} \cdot \hat{n}_2)(\mathbf{j} \times \hat{n}_2)]. \quad (104)$$

Let's assume for the time being that  $L_1 \ll L_2$ , so the system is sufficiently hierarchical that  $\mathbf{j}_2$ ,  $\mathbf{e}_2$  are constants. Note for reference that

$$t_{LK} \equiv \frac{L_1}{\mu_1 \Phi_0} = \frac{1}{n_1} \left( \frac{m_1 + m_2}{m_3} \right) \left( \frac{a_2}{a} \right)^3 (1 - e_2^2)^{3/2}. \quad (105)$$

Here,  $n_1 \equiv \sqrt{G(m_1 + m_2)/a^3}$ . Thus,  $1/t_{LK} \propto a^{3/2}$ .

GW radiation (Peters 1964) cause decays of  $\mathbf{L}$  and  $\mathbf{e}$  as

$$\left. \frac{d\mathbf{L}}{dt} \right|_{GW} = -\frac{32}{5} \frac{G^{7/2}}{c^5} \frac{\mu^2 m_{12}^{5/2}}{a^{7/2}} \frac{1 + 7e^2/8}{(1 - e^2)^2} \hat{\mathbf{L}}, \quad (106)$$

$$\left. \frac{d\mathbf{e}}{dt} \right|_{GW} = -\frac{304}{15} \frac{G^3}{c^5} \frac{\mu m_{12}^2}{a^4 (1 - e^2)^{5/2}} \left( 1 + \frac{121}{304} e^2 \right) \mathbf{e}, \quad (107)$$

$$\left. \frac{\dot{a}}{a} \right|_{GW} = -\frac{64}{5} \frac{G^3 \mu m_{12}^2}{c^5 a^4} \frac{1}{(1 - e^2)^{7/2}} \left( 1 + \frac{73}{24} e^2 + \frac{37}{96} e^4 \right). \quad (108)$$

Here,  $m_{12} \equiv m_1 + m_2$ . The last GR effect is precession of  $\vec{e}$ , which acts as

$$\left. \frac{d\mathbf{e}}{dt} \right|_{GR} = \frac{3Gnm_{12}}{c^2 a (1 - e^2)}. \quad (109)$$

Given this system (from LML15 + LL18), we can then add the spin-orbit coupling term (from de Sitter precession), which is given in LL18 to be

$$\frac{d\hat{\mathbf{S}}}{dt} = \Omega_{SL} \hat{\mathbf{L}} \times \hat{\mathbf{S}}, \quad (110)$$

$$\Omega_{SL} \equiv \frac{3Gn(m_2 + \mu/3)}{2c^2 a (1 - e^2)}. \quad (111)$$

Note that  $\mu$  is the reduced mass of the inner binary. We can drop the back-reaction term since  $S \ll L$ . Thus,  $\Omega_{SL} \propto a^{-5/2}$ .

What is observed is that, as this system is evolved forward in time and GR coalesces the inner binary,  $\theta_{sl} \equiv \arccos(\hat{\mathbf{S}} \cdot \hat{\mathbf{L}})$  goes to  $90^\circ$  consistently. The relevant figure is Fig. 19 of LL18, which shows that for a close-in, low-eccentricity perturber ( $\bar{a}_{\text{out,eff}} \propto a_{\text{out}}$ ), the focusing is significantly stronger. Note that initially,  $I \equiv \arccos(\hat{\mathbf{L}} \cdot \hat{\mathbf{L}}_2) \approx 90^\circ$  while  $\theta_{sl} \approx 0$ .

Next, when accounting for GR, we should let  $a$  evolve as above. Note that since  $\mathbf{j}$  and  $\vec{e}$  are our dynamical variables, we should use  $\mathbf{j} \equiv \sqrt{1 - e^2} \hat{\mathbf{L}} = \sqrt{1 - e^2} \frac{\mathbf{L}}{\mu \sqrt{Gm_{12}a(1 - e^2)}}$  and rewrite

$$\left. \frac{d\mathbf{j}}{dt} \right|_{GW} = \frac{1}{\mu \sqrt{GMa}} \left. \frac{d\mathbf{L}}{dt} \right|_{GW} - \frac{\mathbf{j}}{2a} \left. \frac{da}{dt} \right|_{GW}. \quad (112)$$

To double check, we should verify that  $\left. \frac{d(j^2 + e^2)}{dt} \right|_{GW} = 0$ , which can be verified as (Let's set  $G = M = \mu = a = c = 1$  for convenience)

$$\frac{1}{2} \frac{d(j^2 + e^2)}{dt} = \mathbf{j} \cdot \frac{d\mathbf{j}}{dt} + \mathbf{e} \cdot \frac{d\mathbf{e}}{dt}, \quad (113)$$

$$= \mathbf{j} \cdot \left[ \left( -\frac{32}{5} \frac{1 + 7e^2/8}{(1 - e^2)^2} \right) \hat{\mathbf{L}} - \frac{\mathbf{j}}{2} \left( -\frac{64}{5} \frac{1 + 73e^2/24 + 37e^4/96}{(1 - e^2)^{7/2}} \right) \right] + \mathbf{e} \cdot \left( -\frac{304}{15} \frac{1 + 121e^2/304}{(1 - e^2)^{5/2}} \right) \mathbf{e}, \quad (114)$$

$$= \left( -\frac{32}{5} \frac{1 + 7e^2/8}{(1 - e^2)^{3/2}} \right) + \left( \frac{32}{5} \frac{1 + 73e^2/24 + 37e^4/96}{(1 - e^2)^{5/2}} \right) + e^2 \left( -\frac{304}{15} \frac{1 + 121e^2/304}{(1 - e^2)^{5/2}} \right), \quad (115)$$

$$= \frac{1}{15(1 - e^2)^{5/2}} \left[ -96(1 - e^2) \left( 1 + \frac{7e^2}{8} \right) + 96 \left( 1 + \frac{73e^2}{24} + \frac{37e^4}{96} \right) - 304e^2 \left( 1 + \frac{121e^2}{304} \right) \right]. \quad (116)$$

This can be verified to vanish upon term-by-term examination indeed.
